

Title

A pragmatic evaluation of guided behavioural activation for major depressive disorder: a comparison across recruitment settings

Abstract

A multicentre investigation examined guided behavioural activation against standard care in 496 adults with major depressive disorder. Results were consistent with the prespecified hypothesis for depressive symptom severity, while treatment exposure and adverse events were broadly comparable between groups. Generalisability may be reduced because participating sites had established research infrastructure. The study team documented variation in delivery intensity across participating sites. This report is from a parallel-group randomized controlled trial comparing Control: usual care vs Intervention: pharmacist medication review + telemonitoring coaching.
