

Title

Efficacy and safety of guided behavioural activation for major depressive disorder: an outpatient outcomes study

Abstract

This prospective study assessed guided behavioural activation against standard care in 409 adults with major depressive disorder. Results were consistent with the prespecified hypothesis for depressive symptom severity, while treatment exposure and adverse events were broadly comparable between groups. The study was not powered to detect uncommon adverse events. Recruitment pathways and treatment fidelity were examined to support interpretation of the estimates. This report is from a parallel-group randomized controlled trial comparing Control: placebo education vs Intervention: telemonitoring coaching + dietary counselling.
