

Title

Maternal Satisfaction and Birth Experience: Comparing Early Term versus Standard Timing Delivery in Hypertensive Pregnancy

Abstract

A cohort of 357 women with hypertension across pregnancy enrolled in a randomised trial evaluating maternal experience outcomes. One group underwent planned delivery before 39 weeks, while the other followed conventional expectant care. Maternal questionnaire responses indicated comparable overall satisfaction between groups, with mean domain scores showing no clinically meaningful variation across measures of perceived support, personal autonomy, confidence in safety, and involvement in care planning. Open-ended feedback from participants was predominantly affirmative in both arms. Subgroup examination based on demographic characteristics revealed no significant differential effects. Additional clinical endpoints such as serious maternal or fetal complications did not differ substantially between the delivery timing approaches. These findings suggest that for pregnant women with controlled hypertension and uncomplicated courses, the timing of labour induction does not substantially modify the subjective experience of childbirth. Future decision-making regarding delivery timing may be guided more by clinical risk indicators and resource considerations rather than anticipated impact on maternal satisfaction.
