

Title

Efficacy of Dietary Spice Components in Modifying Chronic Pain: A 3-Week Randomised Crossover Trial

Abstract

Thirty adults with moderate chronic pain completed a randomised crossover study examining dietary spice interventions. Participants consuming turmeric-based formulations reported meaningful reductions in daily pain intensity compared to baseline periods. Statistical testing confirmed the significance of these improvements. When comparing various dosing levels of turmeric alone, as well as turmeric combined with pepper bioenhancer, both showed comparable benefit, though the distinction between individual dose levels did not reach statistical significance. Medication use for pain relief showed no between-group differences. No serious adverse events were reported during the study period. These results indicate that incorporating turmeric into daily intake demonstrates measurable analgesic potential in this population. The bioenhancer properties of pepper did not substantially amplify outcomes in this preliminary assessment. Future research with larger samples and longer intervention windows may clarify optimal dosing and whether combining multiple botanical agents provides added benefit.
