

Efficacy of Targeted Immunotherapy in Advanced Lung Cancer

John Smith, Jane Doe

ABSTRACT

Patients with advanced lung cancer historically face poor prognoses and high toxicity from standard treatments. To evaluate a more effective and tolerable therapeutic pathway, we conducted a phase 3, randomized, controlled clinical trial across 30 oncology centers involving 616 patients. Participants were randomized 1:1 to receive either targeted immunotherapy as a single-agent intravenous infusion or standard chemotherapy. The primary endpoint evaluated was overall survival. The trial demonstrated a substantial survival benefit for the intervention, with a median overall survival of 22.0 months for patients receiving targeted immunotherapy compared to 10.7 months for those receiving standard chemotherapy ($P < 0.001$). Severe treatment-related adverse events occurred in 15% of the intervention group, compared to 38% of the control group. These results indicate that targeted immunotherapy significantly extends survival and offers a superior safety profile compared to standard chemotherapy, strongly supporting its use as a primary standalone therapy.

Trial Context

Underlying randomized controlled trial comparing targeted immunotherapy monotherapy with standard chemotherapy in patients with advanced lung cancer.
